Abstract A multiresidue analysis method for the simultaneous determination of 203 pesticides in soybean was developed using solid-phase extraction (SPE) and gas chromatography–tandem mass spectrometry (GC–MS/MS). Scheduled multiple reaction monitoring by GC–MS/MS was optimized in electron ionization mode. The target pesticides satisfied the method limit of quantitation below 0.01 mg/kg, and an excellent instrumental repeatability was obtained. The calibration curve correlation coefficients ($r^2$) for 201 (99.0%) pesticides were $\geq 0.990$. The Multi-class Pesticide Multiresidue Method (No. 2) of the Korea Food Code was scaled down and applied for efficient sample treatment. Soybean sample (10 g) was extracted with 20 mL acetonitrile. The sample was filtered, partitioned with sodium chloride, and centrifuged. The supernatant (8 mL) was subjected to cleanup with a florisil SPE cartridge (500 mg), and the final extract was subjected to GC–MS/MS analysis. To remove fat, further liquid–liquid partitioning with n-hexane/acetonitrile was conducted before the SPE cleanup, and this procedure was compared to the non-partitioning procedure. The percentage of pesticides satisfying the recovery range of 70–120% with a relative standard deviation $\leq 20\%$ in the non-partitioning and partitioning procedures were 87.2% and 78.8% at 0.01 mg/kg and 88.2% and 76.8% at 0.05 mg/kg, respectively. The average matrix effect value (%) was 5.5%. This miniaturized analytical method can be successfully applied for rapid and sensitive monitoring of multiresidues in soybean and related agricultural products.

Keywords GC–MS/MS · Multiresidue · Pesticide · Positive list system · Solid-phase extraction · Soybean

Introduction

Pesticide residues in agricultural products are regulated by governmental authorities to secure the health of populations. The current food safety system for pesticide residues in the Republic of Korea is based on the negative list system (NLS), in which the pesticide residue according to maximum residue levels (MRLs) list is regulated [1]; however, the positive list system (PLS) will be enforced from 2019 onward instead of the NLS. In the PLS, the levels of pesticide residue should be below 0.01 mg/kg when an MRL has not been established in corresponding crops and food [2]. The PLS has been successfully implemented for many years in various countries including the USA, Australia, Canada, Hong Kong, Japan, Taiwan, and the European Union (EU). In Korea, the PLS has been implemented for tropical and subtropical fruits, nuts, and seeds since December 31, 2016, and will be applied to all agricultural products starting on January 1, 2019 [1].

The introduction of the PLS requires high-throughput analytical techniques with reliable accuracy to determine trace concentrations of hundreds of pesticides in various food matrices, with a short analysis time. Gas chromatography–tandem mass spectrometry (GC–MS/MS) has been widely used as an analytical tool to simultaneously detect...
and quantify multiresidue pesticides with high efficiency [3–5]. The multiple reaction monitoring (MRM) mode of GC–MS/MS is able to distinguish target analytes from interferences with high sensitivity and selectivity. The Multiclass Pesticide Multiresidue Method (No. 2) of the Korea Food Code is a powerful sample treatment procedure enabling the determination of pesticide multiresidues in various agricultural products [6]. In this method, the florisil solid-phase extraction (SPE) is applied, using polar magnesium silicate for adsorption chromatography in a cleanup step. Florisil has strong purification characteristics for pesticides from fatty samples due to its ability to preferentially retain some lipids [7]. Polar matrices such as triglycerides and phytosterols are also easily removed from the sample extract by associating with the surface of florisil [8].

Soybean is one of the most important agricultural products worldwide due to its higher protein content than other vegetables, and it is cultivated on an approximately 6% of the world’s arable lands [9]. It has a high fat content (20% of total weight) [10] and is thus used as an edible oil. There are 112 and 481 MRLs for soybean established in Korea [11] and the EU [12], respectively; however, few studies have analyzed pesticide multiresidues in soybean.

In this study, we selected 203 GC-amenable pesticides from the soybean MRL lists of Korea and the EU and developed a simultaneous analytical method using GC–MS/MS. The scheduled MRM mode of GC–MS/MS was used as an effective throughput of target pesticides. The official Multiclass Pesticide Multiresidue Method (No. 2) of the Korea Food Code was scaled down and validated with 203 pesticides. To remove fat, a liquid–liquid partitioning method using n-hexane/acetonitrile was also investigated for comparison with the non-partitioning method.

Materials and methods

Chemicals and reagents

Each of pesticide standard (analytical grade) and stock solution was purchased from ChemService (West Chester, PA, USA), Wako Pure Chemical Industries (Osaka, Japan), Dr. Ehrenstorfer (Augsburg, Germany), Sigma-Aldrich (St. Louis, MO, USA), AccuStandard (New Haven, CT, USA), and ULTRA Scientific (North Kingstown, RI, USA) and gratefully obtained from the Ministry of Food and Drug Safety (Republic of Korea). High-performance liquid chromatography (HPLC)-grade acetonitrile, acetone, and n-hexane were sourced from Fisher Scientific (Seoul, Republic of Korea). Sodium chloride (NaCl, 99.0%) was obtained from Samchun (Gyeonggi-do, Republic of Korea). Diethylene glycol (≥ 99.0%) was purchased from Sigma-Aldrich. A Strata-FL-PR florisil cartridge (500 mg/6 mL) was obtained from Phenomenex (Torrance, CA, USA).

Instrumental conditions (GC–MS/MS)

Pesticide multiresidues were analyzed with the GCMS-TQ8040 triple quadrupole mass spectrometer (Shimadzu, Kyoto, Japan). A Topaz glass liner (3.5 mm) with wool (Restek, Bellefonte, PA) was installed in the inlet, and the capillary column was an Rxi-5Sil MS (30 m × 0.25 mm i.d., 0.25 μm df, Restek). The inlet temperature was 280 °C, and the injection volume was 2 μL. The splitless (75 s) mode was used during sample injection. The oven temperature program was initialized at 70 °C (held for 2 min), ramped to 160 °C at 15 °C/min, increased to 260 °C at 5 °C/min, and finally ramped to 300 °C at 15 °C/min (held for 8 min). The total program time was 38.7 min. Helium (≥ 99.999%) was used as a carrier gas, and the flow rate (constant) was 1.0 mL/min.

For MS/MS, the electron ionization (EI) mode was selected for ionization and the electron voltage was 70 eV. The ion source and transfer line temperatures were 230 and 280 °C, respectively. The collision inductive dissociation (CID) was assisted with argon (≥ 99.999%) gas. The detector voltage was 1.4 kV (constant). Data processing was conducted using LabSolutions (GCMS solution, version 4.30).

MRM profile optimization

Each pesticide standard solution was injected into GC–MS/MS, and a full-scan spectrum of each target analyte was obtained (m/z range: 50–500). From the spectrum, one or two fragment(s) or molecular ion(s) were selected as a precursor ion(s) considering their specificity. Each precursor ion was subjected to a product scan using CID with various collision energies, and two optimum product ions were selected as qualifier and qualifier ions, respectively.

Method limit of quantitation, instrumental repeatability, and linearity of calibration

The method limit of quantitation (MLOQ) was calculated from the instrumental limit of quantitation (ILOQ), injection volume, and sample equivalent in the final extract using Eq. (1):

$$\text{MLOQ (mg kg}^{-1}) = \frac{\text{ILOQ (ng)}}{\text{injection volume (μL)}} \times \frac{1}{\text{sample equivalent (g mL}^{-1})}. \quad (1)$$
Matrix-matched standards in the soybean samples were injected into GC–MS/MS, and the lowest amount that satisfied a signal-to-noise ratio (S/N) ≥ 10 for each pesticide was selected as the ILOQ. The instrumental repeatability for each pesticide was verified with the relative standard deviation (RSD) of the peak area by injecting and analyzing a matrix-matched standard seven times. The linearity of calibration expressed as correlation coefficient ($r^2$) was investigated using matrix-matched standards (0.002–0.2 mg/L). A weighting regression factor (1/x) was used to minimize calculation errors at low concentrations.

Recovery test without a defatting step using n-hexane/acetonitrile partitioning

Sample treatment was conducted using Multiclass Pesticide Multiresidue Method (No. 2) with a modification of sample weight (i.e., a 1/5 reduction). Ten grams of macerate was spiked at 0.01 mg/kg ($n = 3$) and 0.05 mg/kg ($n = 3$) of 203 pesticides, and 6 mL water was added to let the entire sample soak the water before extraction with 20 mL acetonitrile. The tube was shaken for 2 min at 1200 rpm using the Geno/Grinder® (1600 MiniG SPEX Sample Prep, Metuchen, NJ, USA), and then, the sample was subjected to suction filtration under vacuum. The extract was treated with 3 g NaCl, shaken, and centrifuged for 5 min at 3500 rpm using the Combi 408 centrifuge (Hanil Science Industrial Co., Ltd., Republic of Korea). The supernatant (8 mL) was combined with 0.2 mL of 2% diethylene glycol (keeper solution) in acetone, evaporated with a rotary evaporator (40 °C), and reconstructed in 4 mL of 20% acetone in n-hexane (v/v).

For the SPE cleanup step, a florisil cartridge (500 mg) was conditioned with 5 mL n-hexane and 5 mL of 20% acetone in n-hexane. Reconstructed extract (4 mL) was loaded and the cartridge was eluted again with 5 mL of 20% acetone in n-hexane. The eluted extracts were evaporated to dryness under a stream of nitrogen gas. The sample was dissolved in 2 mL acetonitrile, and 0.8 mL of the extract was matrix-matched with 0.2 mL of acetonitrile. Finally, the aliquot (2 µL) was injected into GC–MS/MS for analysis. The sample was equivalent to 1.6 g per 1 mL in the final extract.

Recovery test with a defatting step using n-hexane/ acetonitrile partitioning

Ten grams of soybean macerate containing 0.01 mg/kg ($n = 3$) and 0.05 mg/kg ($n = 3$) of 203 pesticides was subjected to extraction, filtration, NaCl partitioning, and evaporation as described above. Then, the extract was dissolved in 30 mL n-hexane saturated with acetonitrile and partitioned with 30 mL acetonitrile saturated with n-hexane (twice). The lower layers from each partition were collected, treated with 0.2 mL of 2% diethylene glycol in acetone, and evaporated with a rotary evaporator (40 °C) for the next cleanup step and analysis as described above. Recovery of this partitioning step with n-hexane/acetonitrile in this method was compared to the method without a partitioning (non-partitioning) procedure.

Matrix effect

The matrix effect was verified to compare the slope of calibration from a matrix-matched standard and from a solvent-only standard. Matrix effect values (%) for each pesticide were calculated using Eq. (2):

\[
\text{Matrix effect} \% = \left( \frac{\text{Slope of matrixmatched standard calibration}}{\text{Slope of solventonly standard calibration}} - 1 \right) \times 100.
\]

Results and discussion

MRM optimization and MLOQ

Using each pesticide standard, MRM profiles were successfully established and also verified under GC conditions. The detailed MRM profiles and retention time ($t_R$) for 203 pesticides are given in Table S1.

The ILOQ was determined by the S/N method [13]. Matrix-matched standard mixtures at 0.004, 0.01, 0.02, 0.04, 0.1, 0.2 and 0.4 ng (equivalent to 0.002, 0.005, 0.01, 0.02, 0.05, 0.1 and 0.2 mg/L of the matrix-matched standard solutions) were injected into the GC–MS/MS, respectively, and the lowest amount satisfying an S/N ≥ 10 on the chromatogram was selected as the ILOQ. The MLOQ was derived from the ILOQ, injection volume (2 µL), and sample equivalent (1.6 g/mL) (see Eq. 1). As a result, all of the pesticides had MLOQ < 0.01 mg/kg (193 compounds for < 0.002 mg/kg, 7 for 0.003 mg/kg, and 3 for 0.006 mg/kg) (Table S2). This indicates that these pesticides are applicable for the PLS, in which the residue level should be under 0.01 mg/kg for a pesticide without the Korean MRL lists [1]. Thus, this analytical method can determine pesticide multiresidues in soybean and related crop with sufficient sensitivity.

Instrumental repeatability

Instrumental repeatability is a parameter that ensures the integrity of instrumental performance for target compounds [14, 15]. A repeatability test was conducted by consecutively injecting matrix-matched standard solutions at 0.01
and 0.05 mg/L (n = 7, respectively), and the area RSD was verified for each pesticide. The average RSDs of the 203 target analytes were 2.4% at 0.01 mg/L and 1.4% at 0.05 mg/L (Table S2), with a better repeatability at higher concentration. Among the pesticides, 200 (98.5%) compounds at 0.01 mg/L and 203 (100.0%) at 0.05 mg/L were below than 10% (Table 1). This indicates that GC–MS/MS had excellent performance for the analysis of most pesticides. The RSDs for three (1.5%) of the pesticides at 0.01 mg/L fell within 10.0–12.4%. These analytes still had an acceptable repeatability, considering that the RSD criterion for recovery was ≤ 20% according to the SANTE guidance document [16].

**Linearity of calibration**

The linearity of matrix-matched calibration (weighting regression factor, 1/x) was determined. Among the 203 target analytes, 201 (99.0%) pesticides had a $r^2 \geq 0.990$ (Fig. 1). Only the $r^2$ values of methoxychlor and p,p′-DDT were lower at 0.980–0.990 and < 0.980, respectively. Therefore, precise quantitative analysis was possible for most of the pesticides. The $r^2$ values for the 203 pesticides are presented in Table S2.

**Recovery without n-hexane/acetonitrile partitioning (non-partitioning)**

For efficient sample treatment, the sample size and extraction solvent volume used in the Multiclass Pesticide Multiresidue Method (No. 2) were reduced from 50 to 10 g and 100 to 20 mL acetonitrile, respectively. During the evaporation at 40 °C, diethylene glycol in acetone, a keepr solution, was added to each sample to prevent some volatile pesticides from evaporating with the solvent [17]. To maintain the optimal and rugged performance of the florisil SPE, the sorbent was prevented from drying out during the conditioning, sample loading, and elution steps, as described by Mutavdžić et al. [18].

The recovery test was conducted at 0.01 and 0.05 mg/kg. It was found that 177 (87.2%) and 179 (88.2%) of all

203 pesticides satisfied the acceptable recovery criteria [16] of 70–120% with an RSD ≤ 20% (Table 2) at 0.01 and 0.05 mg/kg, respectively. The number of pesticides satisfying the criteria at 0.05 mg/kg was slightly higher than at 0.01 mg/kg. These compounds were detectable with a high reliability and precision. The number of pesticides and its percentage satisfying the criteria at 0.01 mg/kg were higher than those in modified QuEChERS (quick, easy, cheap, effective, rugged, and safe) methods with fatty matrices such as soy-based nutraceutical products and avocado [19, 20]. The number of pesticides outside the recovery criteria (30–70%) but that still within an RSD ≤ 20% were 26 (12.8%) and 24 (11.8%) at 0.01 and 0.05 mg/kg, respectively. The recovery of these compounds was consistent [16] and therefore acceptable for screening purposes. The detailed recovery rates for 203 pesticides are given in Table S3.

**Recovery with n-hexane/acetonitrile partitioning**

Because soybean has a high fat content (20% of total weight) [10], a defatting procedure could be used to

The scatter plot between recovery and relative standard deviation (RSD) of 203 pesticides for partitioning and non-partitioning procedures (0.05 mg/kg) (Fig. 2). The number of pesticides satisfying the recovery criteria in this procedure was slightly lower than when a defatting procedure was not applied (see Table 2). The scatter plot between recovery and RSD (Fig. 2) for individual pesticides indicated that a non-partitioning procedure resulted in better recovery and a more constant RSD than when a partitioning procedure was applied. Some of the pesticides with a higher log P remained in the hexane layer during partitioning, resulting in low recovery. To verify the cleanup efficiency, scan chromatograms of control soybean samples were compared (Fig. S1). At $t_R$ values of 5.0–10.0 min and 25.5–27.0 min, more impurities were detected when the non-partitioning procedure was applied than when the partitioned procedure was applied, whereas larger peaks were observed when the partitioning procedure was applied at a $t_R$ value of 31.0 min or greater. There were no significant differences in the cleanup between the procedures. From the results, the preparation procedures without n-hexane/acetonitrile partitioning (non-partitioning) were considered as the most appropriate soybean treatment methods for GC–MS/MS analysis.

Matrix effect

Matrix effect is a common phenomenon when analyzing pesticides via GC [21]. A scatter plot between the $t_R$ and matrix effect (Fig. 3) indicated that the signals of most analytes were enhanced by co-eluent matrices throughout the $t_R$. Many previous studies have reported signal enhancement by crop matrices in GC–MS or GC–MS/MS [22–24]. The average matrix effect for target pesticides was 5.5%. The range of the matrix effect was classified into six groups with three categories (soft, medium, and strong effect) as shown in Fig. 4 [25, 26]. The most of the
pesticides (96.0%) were included in the soft matrix effect range between −20 and 20%. Pesticides within this effect range do not require matrix-matching because this effect is negligible [27]. However, matrix-matching is required for compounds in the medium matrix effect range (−20 to 20%) and strong (<−50% or >50%) groups correct quantitation via GC–MS/MS [28]. The matrix effect values for the 203 pesticides are given in Table S3.

Acknowledgments This study was conducted with financial support from the Korea Ministry of Food and Drug Safety (16122MFDS020).
